Cusick, L.C. and Y. Gorokhovich. 2003. Reconstruction of Paleogeographic History of the Hudson River at Newly Exposed Pleistocene Strata at Bear Mountain. Section I: 1-32 *In* J.R.Waldman & W.C. Nieder (eds.), Final Reports of the Tibor T. Polgar Fellowship Program, 2002. Hudson River Foundation.

ABSTRACT

Sedimentary deposits provide historical records regarding the glacial environment during periods of ice sheet and glacier expansion and retreat. The best method to decipher these environments is to study sediments in their natural settings. Recently exposed horizontal strata at Jones Point, New York, made it possible to analyze and reconstruct the paleogeographic environment of Hudson River during the late Pleistocene at this location. Field observations and dry sieving granulometric analyses of each of the fourteen layers in the strata revealed deltaic-fluvial processes, both large-scale and seasonal, and localized flood events. These depositional changes took place in the Pleistocene epoch, during the Woodfordian sub-stage of the Late Wisconsinian stage, approximately 14,000 years ago, as the climate warmed and glaciers quickly and repeatedly advanced and retreated. Glacial directional movement and formation of moraines and glacial lakes, such as Lake Hudson and Lake Albany, have resulted in the reversal or slowing down of the flow of water in the Hudson River Valley, thus changing the direction and processes of sediment deposition. Measured angles of the layers of deposits established three distinguishable directions of flow that took place at Jones Point, New York: from the northwest, northeast and east. In addition, Global Positioning System readings of elevation indicated that the rates of isostatic rebound at our sites correspond with the results from a previous report.

INTRODUCTION

The geology of the Hudson Valley in New York State is extremely diverse from the northern Adirondacks south to the Palisades. The Hudson River itself has been active geologically through the cycles of erosion, transportation and deposition of sediments. Glacial activity considerably affected these processes during the Pleistocene epoch. As glaciers migrated southward, they carried vast amounts of sediments including clay, silt, sand, pebbles, rocks and boulders. Transportation and preservation of this material occurs within the glacier (englacial zone), on the surface and edges (supraglacial zone), and on the bottom of the glacier in contact with the bedrock (basal or subglacial zone) (Reading 1986). It is due to the movement of the glacier and its bedrock-basal zone contact where the majority of the erosion and transportation of parent rocks takes place (Reading 1986).

As the climate warmed towards the end of the Pleistocene in the Wisconsinian age, lasting from 24,000 to 12,600 years ago, there was major glacial retreat (Connally and Sirkin 1973). However, colder periods persisted and the glaciers still advanced periodically from different directions, though not as far as the Ronkonkoma moraine on Long Island (Borns 1973). Within the Lower Hudson River valley region of New York State, the Hudson Highlands, this intermittent glacial advance and retreat continued at the leading edges of the glaciers. Several studies describe glacial movements in detail (Thwaites 1946, Reading 1986, Sanders and Merguerian 1998).

Till deposits are poorly sorted, unstratified sediments consisting of a clay and sand matrix with inclusions of gravel, pebbles, and boulders. They indicate the presence of glacier activity and are found throughout the Hudson River Valley and surrounding vicinity (Press and Siever 2001).

However, to describe the specifics of a glacial paleoenvironment scientists need more information regarding the presence of glacial features that leave stratified layers of deposits. Vegetative cover and increasing regional development make it difficult to find an undisturbed, horizontal sequence of layers that may generate an ideal stratigraphic sequence study.

The finding of the exposed horizontal strata at Jones Point made it possible to analyze and reconstruct the paleogeographic environment of Hudson River during the late Pleistocene at this location. The location of our research sites are approximately ¼ and ½ mile southwest of Jones Point, NY, on the eastern and western sides, respectively, of Route 9W/202 (Figs.1 & 2). This newly-exposed strata, due to a localized landslide at the first site (Fig. 3), is visible from the road as one travels north on Route 9W and was first noticed in autumn of 2001 by Dr. Yuri Gorokhovich, geology professor at Purchase College. We noticed the second site, a functioning small-scale sand and gravel pit, while looking for other exposures in the area along Route 9W/202 (Fig. 4). Since it is still functioning as a gravel pit, removal of gravel and sand exposes new material from each layer altering the face of the strata.

The first objective of the research was to reconstruct the paleogeographic history of the area during the late Wisconsinian stage using granulometric and mineral analysis. The second objective was to estimate the isostatic rebound rate of the area, i.e., uplift due to large-scale glacial retreat at the end of the Pleistocene epoch.

Granulometric and mineral analysis will define the grain size distributions and the mineral composition of each sample of the stratigraphic sequence of sediment particles. To establish the origin of the parental material, we will implement the glycerin density-separation technique to allow the identification of the mineralogical associations between layers in exposed strata. This procedure segregates the heavy fractions of sediment containing iron and magnesium minerals from the light fraction containing silica rich minerals.

The fact that the top of the exposed strata are found on a high elevation mark, approximately 100 feet above sea level according to the United States Geological Survey 7.5 minute Peekskill quadrangle, makes it possible to estimate the rate of isostatic rebound for the area. A Global Positioning System unit was used to locate the sites and measure the elevations of each site in order to complement past research carried out by Connally and Sirkin in 1984 regarding isostatic rebound of the Mid-Hudson Valley.

Note the downward dip of the layers between horizontal layers in the middle of the image.

Methods

Initial field methods in February 2002 included photographing and sketching the cross-section of the strata, recording the color, grain texture and measuring the thickness of each of the fourteen distinct layers at the first site, JP1. Also noted were such features as cross-bedding, drastic differences in grain-size, as well as noticeable changes in dip and angle between the separate layers.

Using a cylindrical open-ended container, we collected three representative samples from each layer in labeled sampling bags. On each was marked the layers starting with "A" as the uppermost layer and continuing down to layer "L" at the bottom.

Unsorted landslide debris covering strata below layer L made it impossible to obtain additional samples of layers below this point. Layer K contained predominantly cobbles and boulders too large to fit into the sample bags, therefore, we only removed a few hand samples and left this layer for morphological analysis in the field.

After allowing the samples to air-dry for approximately two weeks, we weighed the contents of the first sample bag from layer A to the nearest $1/100^{th}$ gram. We then emptied the sample into the uppermost sieve, greater than 8mm, (phi value of -3), of the sieve stack, allowing separation of grains throughout the stack, seven sieves in total, each sieve decreasing by one-half in size as the grains pass through the sieves. Grains less than 0.0062mm in diameter (phi-value = +4), were collected in the bottom pan. Note that the sieve for grain-size 4mm (phi-value = -2), was not used in the analysis as the main focus of this research was the finer sand size grains, less than 2mm, and the localized processes involved in the formation of each layer in the sequence of the strata. By placing the sieve stack on the electric sieve shaker for 10 minutes at setting number 5, we continued separation of the grains. We analyzed the contents of the sieve containing the larger grains; layer K with most grains larger than 8mm, using visual morphological analysis in the field as well as in the lab.

Upon completion of the sieve shaking, the contents of each sieve layer, starting with the coarsest (>8mm), were emptied onto a clean board and the screen on the sieve was carefully cleaned of lodged particles, adding the collected grains to the present fraction. This fraction was weighed and recorded, to the nearest one-hundredth of a gram, and deposited into an envelope for later mineralogical analysis. Each grain size fraction for the stack required repeating these steps and noting the location, date, sample layer, sample number, range of the grain-size and the weight for the respective fraction.
